005 OWNER'S MANUAL

Copyright - 1982 by SEGA/Gremlin, All Rights Reserved

## INTRODUCTION

005 is an electronics game that makes extensive use of digital integrated circuitry and television monitor concepts. This manual is intended for the use of the maintenance technician who possesses a general working knowledge of solid state circuitry, microprocessor and digital integrated circuitry, and video monitor concepts. Any individual NOT knowledgeable in these areas SHOULD NOT attempt repair of the electronic portions of the game, referring rather, to a competent technician.

SEGA/Gremlin's G-80 system will make troubleshooting easy. Each board has a separate function and most problems can immediately be isolated to a single board. The individual boards contain less circuitry than if they were combined on one or two boards. This results in faster and easier servicing. The new G-80 card cage system provides for a self-test feature (located on the CPU board) in addition to giving SEGA/Gremlin more flexibility in designing new games compatible with the revolutionary CONVERT-A-GAME™. Increased ROM capability and the addition of a quality synthesis (in some games) means that new SEGA/Gremlin games will be more exciting and certainly more profitable. Comments or questions about our games are welcome, and should be directed to:

## Game Set-Up and Inspection

### 1. Inspection

- a) Before plugging in your new game, inspect it closely to spot any possible shipping damage. Check to ensure the graphics are in place, the monitor is not damaged and that the overall cabinet is in good condition.
- b) Open the coin mechanism door and inspect the inside of the game electronics compartment. Be sure no components or connectors have come loose. Proper connector fittings must be checked before game power is applied. Check all related connectors for good contact. Although disconnected connectors are easily spotted, poor contacts are difficult to locate. The connectors should therefore be pushed in firmly and then loosened to spot poor connections.
- c) Are the fuses intact? There are five fuses (not counting the monitor fuses which are detailed in the monitor manual for this game). One fuse is located on the AC junction box. The other four are on the power supply PC board.

### 2 Voltage Selection

- a) Before plugging in your game, make sure that the game voltage is correct for your location. Locate the two leads from the AC junction box to the power transformer. For 110 VAC, they should be connected to terminals 1 and 3 on the power transformer. For 100 VAC, connect 1 and 2, and for 220 VAC applications, they should be connected to 1 and 4.

You will also notice on the AC junction box that there is a safety interlock switch. When the front panel is in place the switch is depressed and the game receives power. Removing the front panel, the switch returns to its original position and the power is cut off from the game. For servicing, this switch can be pulled out and power will be restored.

### 3. Game Specifications

Power	100 VAC, 60 HZ (nominal), 150 watts max
	110 VAC, 60 HZ (nominal), 150 watts max
	220 VAC, 60 HZ (nominal), 150 watts max
Dimensions	25 1/2 inches wide x 30 1/4 inches depth (64.8 cm wide x 76.8 cm depth)
	72 1/2 inches height (184.2 cm height)

### 4. Important Notes

a) The following notes are included in compliance with FCC rules:

WARNING: This equipment generates, uses, and can radiate radio frequency energy and if not installed and used in accordance with the instruction manual, may cause interference to radio communications. As temporarily permitted by regulations, it has not been tested for compliance with the limits for Class A computing devices pursuant to Subpart J of Part 15 FCC Rules, which are designed to provide reasonable protection against interference in which case the user at his own expense will be required to take whatever measures may be required to correct the interference.

b) Miscellaneous

Never remove circuit board connections while power is on.

Never replace any components with anything other than exact replacement parts.

DO NOT replace fuses with anything other than the proper value. A blown fuse indicates an overload condition within the game. Replacing the fuse with a higher value can cause severe damage to internal components, if an overload occurs.

## 5. Control Panel Removal

With the door to the game electronics compartment open, reach under the control panel and flip the fasteners on both sides of the control panel. The panel will now swing outwards. Disconnect the control panel harness, slide the spring-loaded pins on both sides and remove the control panel.

## 6. Front Plexiglass, Interior Graphics and Graphics Frame Removal

The front plexiglass, which secures the interior graphics, is held in place by the control panel. Release the fasteners on the control panel and swing it down. Directly under the front plexiglass, you will notice the graphics frame piece. Grab it in the middle, and pull it from the game. The front plexiglass can now be easily removed by lifting it on the bottom slightly and pulling it outward. The interior graphics are now free to remove. You will also see the graphics frame, which must be removed when taking out the monitor. Simply grip two sides and carefully lift out.

## 7. Card Cage Removal

If it is necessary to remove the card cage for servicing, first pull all the connectors. Then remove the three mounting screws located on the front bracket. The card cage can now be slipped out from under the rear bracket and removed from the game.

## 8. Logo Panel Removal

Remove the front plexiglass, interior graphics and graphics frame as explained above. Logo panel removal is accomplished in one of two ways. Underneath the logo panel, the presence of four mounting screws will dictate the removal of those screws, allowing the speaker board to swing, freeing the logo panel for removal. In the absence of the mounting screws, you will notice a sliding latch, underneath the logo panel and on either side of the speaker. Using a small flat-head screwdriver, slide those latches inward to release the speaker swing panel. Push up on the back portion of this panel, and the logo can now be removed.

9. Monitor Removal

To remove the monitor for servicing or replacement, first open the back panel on the cabinet and disconnect the leads to the monitor. Then, remove the front bezel, interior graphics and spacer frame as explained earlier. Underneath the monitor in the game electronics compartment are four bolts securing the monitor in place. Remove these, pull the monitor on either side and slide it out carefully.

## 005 GAME CONCEPT

Agent 005's mission: evade enemy guards, negotiate warehouses and skating rinks to deliver attache cases to a waiting helicopter, which in turn must engage in an aerial battle with parachute bombs, balloon bombs and an enemy helicopter. Game play begins as 005 parachutes into the scene and picks up an attache case. To make a run for the helicopter straightaway is difficult and accumulates fewer points. His alternative is to duck into either a warehouse or skating rink.

Armed with a stun gun to ward off pursuing guards, 005 can select a building with either 1, 2 or no stun gun cannisters at the entrance. Gas cannisters extend the stun gun's range and add more points. Fallen guards can be passed by other guards, but not by 005. Once inside the building, the scene changes to the interior of that building. In the skating rink, 005 must travel the rink's perimeter, luring the guards onto the ice to stun or evade them. Caution must be exercised here, as 005 can change direction, but cannot stop until he hits the edge of the rink. A successful rendezvous with the helicopter completes that delivery and shifts the scene back to 005 parachuting in to pick up another brief case. Once having been in the skating rink, only warehouses are there to enter, and conversely, if a warehouse was first entered, only skating rinks are available. In later rounds however, both skating rinks and warehouses are displayed. In the warehouse, 005 moves cautiously in the dark, but is pursued once caught in the beam of a guard's flashlight. Again, a helicopter waits to pick up our hero as he makes his way out the far end.

Now in possession of two attache cases, 005 is pursued by an enemy helicopter. Avoiding hedges, shrubbery, descending helicopter bombs, and

ascending balloon bombs, points are scored as 005 shoots balloon bombs, shrubbery or the enemy helicopter. The game ends if 005 is caught, or his helicopter is shot down a total of three times (operator selectable).

#### Scoring

Attache delivered to helicopter	10,000
Guard knocked out	200
Entering a building with:	
No stun gas cannister	300
1 stun gas cannister	400
2 stun gas cannisters	500
Shooting down:	
Shrubbery	20
Balloon Bomb	200
Enemy helicopter (2,000 X no. of brief cases delivered)	5,000+

## G-80 THEORY OF OPERATION

### I. G-80 Boards

The G-80 system consists of several boards that plug into a mother board in a card cage system. This system simplifies repairs and cuts down on interference from outside communications systems. The mother board is crosswired to allow for the boards to be plugged-in in any order. Listed below are the bus pin assignments on the mother board:

1	Ground	A	Ground
2	A15	B	A7
3	A14	C	A6
4	A13	D	A5
5	A12	E	A4
6	A11	F	A3
7	A10	H	A2
8	A9	J	A1
9	A8	K	A0
10	D7	L	D3
11	D6	M	D2
12	D5	N	D1
13	D4	P	D0
14	WAIT	R	RESET
15	INT	S	EDGINT
16	NMI	T	EXT
17	EXT SEL	U	OUT
18	MEMR	V	MEMW
19	INPUT	W	OUTPUT

\*For Development Purposes Only

a) CPU Board

The CPU board is completely timed with the video board. But, for testing purposes it contains its own clock circuit, powered by an 8.000 MHz crystal. Pin 17 is the external clock select and is grounded when the video board is plugged-in. When the external clock pulse comes in through pin T, it goes directly to the CPU and the entire CPU clock circuit is disabled. The WAIT signal, entering in at pin 14 is used to synchronize slower memory accessed by the CPU.

The NMI circuit, entering in at pin 16, contains a switch for activating the built-in-self-test. The self-test system will be explained more fully later.

When the edge interrupt circuit, entering at pin S, goes L0, it triggers an interrupt in the CPU. The CPU stops whatever it is working on, completes the activity required by the interrupt, and then returns to the function it was performing prior to the interrupt. It is a negatively triggered interrupt, which can be disabled by the CPU at any time.

The AC signal, entering in at pin Y, combines with RESET at pin R and the input from the reset switch located on the operator panel to reset the CPU. Disregard PANEL RESET at pin 30. This circuit is used only for system development.

The CPU is a Z80A. A Z80A must always be used as the Z80 is not fast enough to run the G-80 system. U21 is an address bus controller. Eight of the sixteen address lines pass through U21 before addressing the RAMs and Eprom at U25. U25 contains the data for the self-test and contains features common to all games, such as coin acceptance, credit/coin handling, power-up sequence, player 1 or 2 recognition and CPU initialization. U3 is an output port for the CPU and U4 is an input port. Connector P1, pins 24 through 40, shown on sheet 6 is not used. U15, located below U4 on the schematic, decodes memory select on the CPU board. Sheet 7 contains the coin inputs, player inputs and inputs from the operator panel. The coin circuitry contains ICs U6, U39 and U16. U9 is the input port for the coin switches and service switch. Player inputs enter through connector P1, pin 15 through 22.

#### b) SOUND BOARDS

A G-80 Sound Board contains the circuits needed to generate all game sounds other than the speech. The Sound Board Circuits are triggered through 8-bit latches, which are connected to the data bus.

The appropriate 8-bit code on the data bus is then latched to activate the corresponding sound circuit. All Sound Board signals are mixed by an IC op-amp, the output of which is amplified by the power amplifier. In games containing a Speech Board, the Sound Board output is mixed with the speech output on the Speech Board. The result of the mixed signals is then amplified by the power amplifier to drive the speaker.

c) VIDEO BOARD

The video board contains a 15.468 MHz crystal that generates the timing signals for video generation. Because the video board contains twice as many RAMs, it has more extensive graphics capability. Color capability is greatly expanded because of a color RAM, U9, which allows the program to create a wider variety of color schemes. There are 8 shades of red, 8 shades of green and 4 shades of blue. The video board also contains circuitry (U34, U35, U36, U38, U49 and U50) to make the picture "flip" for cocktail table models.

On the G-80 Video I Board is located the VIC Replacement Board. This board is, in part, the equivalent circuit of the VIC chip. It is a simple circuit consisting of a number of counters and multiplexers for generating video timing and addressing video RAM.

d) EPROM Board

The EPROM board contains a relatively simple memory system. It can hold up to 23 2716 EPROMs totalling 46K bytes of memory. U24 and U30 decode all the EPROMs; U25 is the buffer IC to the data bus. In operation, any one of the 23 EPROMs is selected by 5 CPU address lines.

e) POWER SUPPLY

The G-80 power supply incorporates all of the voltages and audio power amplification necessary to power any G-80 based video game. The major

differences between this and other Gremlin power supplies is that the transformer (560-0055) is mounted separately from the PCB/heatsink/chassis combination. This transformer is noticeably larger than previous units, mainly because it has isolation windings for driving X-Y color monitor as well as windings for a raster scan color monitor. There are multiple primary taps available for using 100, 115, or 230 VAC as the input voltage.

Table 1 lists the ratings of the regulated DC voltages ( a standard test load) as well as the ratings of the transformer's windings used to drive the X-Y or raster scan monitor.

TABLE 1

Regulated DC Voltages

+5V @ 6A

-5V @ 1A

+12V @ 1A

-12V @ 1A

AC (monitor) Voltages

X-Y: 92 VCT (voltage center tap) @ 2A

Raster: 100 or 115 VAC @ 0.65A

Voltage Regulator Circuit Description

The +5 volt supply mainly consists of U1 and the TIP141. U1 is a 723 voltage regulator IC which contains a voltage reference, error amplifier, series pass darlington transistor pair and a current limit transistor. Potentiometer R31 (+5V ADJ) divides the 7.15 (NOM) reference to 5.0 volts as the input to pin 5, the noninverting input of the 723's error amp. Pin 4, the inverting input, senses the output voltage. The internal error amp maintains a voltage at U1 pin 10 which is higher than the 5.0V output by an equal amount to the two VBE drops of the TIP141 (a high current

darlington) which acts as a current amplifier, and IR drop across R25. Any change in the output voltage is sensed at pin 4 which causes the error amp to drive pin 10 higher or lower in order to keep the output at a steady 5.0V.

A "foldback" current limiter circuit is composed of R25, R26, R32, Q7 and the internal current limit transistor of U1. This circuit allows the regulator to operate normally until the load current increases to the point where the voltage across the R32 reaches the value which starts turning on the internal current limit transistor. This transistor reduces the output current of the regulator to a fraction of the "knee" current when the output is shorted to ground. This feature greatly reduces the power dissipated in the TIP141 when the output is accidentally short circuited.

Capacitors C20 and C21 frequently compensate the regulator so it won't oscillate and C17 filters high frequencies at the output. Q7 temperature compensates the current limit circuit. Temperature variations of its emitter-base voltage closely match and cancel the base emitter voltage of the internal current limit transistor, the knee current of this regulator would now remain constant over wide temperature variations.

#### Audio Amplifier Circuit Description

The G-80 power supply has provisions for two power amplifiers. Only one is used at present and the foreseeable future. The input signal from the volume control is coupled to differential pair Q2 and Q3 via C5. Resistor R5 sets the input impedance 22K ohms. Resistor R6 sets a current of approximately 2 ma for Q2 and Q3 to divide equally. The voltage gain of Q2 is determined by its emitter current, R7, and the impedance looking into Q1, the second stage of voltage gain. Resistor R8 provides local negative feedback in the emitter of Q1 for increased

open loop linearity while C9 and Q1's voltage gain provide a dominate pole open loop roll-off to ensure stability of the amplifier. Diodes D4 and D5 provide a small amount of turn on bias for the TIP120 and TIP125 darlington current amplifiers. Resistor R22 is bootstrapped by C10 to make R22 look like a current source. This technique allows maximum negative voltage swing for a symmetrical output waveform at full power. Local feedback in the output stage is provided by R14 and R15. The overall voltage gain of the amplifier is set by the ratio of R9 and R10. The actual value is:

$$\frac{R9}{R10} + 1 = \frac{22K}{1K} + 1 = 23 \text{ or } 27\text{db}$$

Capacitor C7 adds additional high frequency compensation and the C8-R10 combination determines the low frequency roll-off point of -3db at 16Hz. The C11-R17 combination provides feedback loop stability in the event that a speaker is not connected. The maximum output is approximately 25 watts into 4 ohms and 15 watts into 8 ohms.

### Adjustments

1. Adjust R31 for 5.0V at the load. This compensates for wiring losses.
2. There are no other adjustments. The tolerances are as follows:

$$-5V \pm 0.2V$$

$$+12V \pm 0.5V$$

$$-12V \pm 0.5V$$

## 1. Self - Test

This is a basic self-test sequence for any G-80 game.

Basic diagnostic test sequence:

- a) CPU RAM
- b) Maskable interrupts
- c) First 1K of game ROM's
- d) Video RAM and Hardware multiplier
- e) Player start buttons
- f) Display screen (visual)
- g) All game ROM's
- h) System input
- i) Game controls
- j) Sounds/Voice

Individualized diagnostics descriptions and procedures:

- a) CPU RAM test - Test all the RAM's on the CPU card before proceeding, the system needs to use this RAM for stack and variables during other tests so if any locations are bad the processor will halt (halt light on).
- b) Maskable interrupts test - Video interrupt is enabled through the output port bit and all maskable interrupts are enabled inside the processor, the CPU then executes several HALT instructions to insure that at least one edge-triggered interrupt has occurred. If no interrupts occur during the test the halt light will remain on constant which is the same result as a bad CPU RAM. This ambiguity can be eliminated by checking the vertical interrupt another way. The system reset/power-up logic will also halt if the video interrupt is not functioning. To try this, press the "Reset" switch.

- c) First 1K of game ROM's test - The first 1K of the first game ROM will be checked for validity. If this portion of the first ROM is bad the system will not be able to proceed because important information defining parameters of the game are stored in this first 1K. If an error occurs during this validity check the CPU. It will hand up and repeatedly flash the halt light.
- d) Video RAM and Hardware multiplier test - The video RAM is tested first in the event that it tests good then the hardware multiplier is checked. If the video RAM is good the message "All Video Ram Good" appears. If a bad video RAM chip is found then the message "Bad Video RAM chip U" appears on the screen along with the chip U number (U#). Due to the fact that sometimes a bad video chip causes the display to be useless, the system also flashes out the bad chips "U#" on the halt light, over and over again seperating the "U#" with a one second on-pulse. The hardware multiplier is used in the game to multiply two 8-bit numbers together to form one 16-bit product. This test performs a select group of multiplications, over 2000 in actuality, design to thoroughly exercise the process of multiplication between the software and the hardware multiplier. The message "Good" or "Bad" are the only indications of functionality with respect to this test.
- e) Player start button test - One of the "two game start" push buttons on the front of the cabinet is very special. The "one player start" button was designed by the system as a way to terminate the test that is currently being run. The reason that these two buttons were tested relatively early in the sequence was so that the remaining tests could use one of them for a termination signal.

To be sure that these two buttons are functioning properly, check it when it is untouched, the status indicated is "0" (for open switch contact) and that when pushed or depressed momentarily the indicated status is "C" (for closed switch contact) during the time the button is down. This notation for switches being in the "Open" or "Closed" state, "0" or "C" will be used throughout the diagnostic sequence whenever the status of a switch is being displayed on the screen.

- f) Screen Test - This test is supplied by the game logic, external to the "CPU ROM", to provide a visual indication of how well the display screen is functioning. Depending on how the game hardware is set up, XY or Raster, or what software version of the game you have, the appearance of this test display may change. Usually there will be some sort of pattern to test beam deflection and colors to check that all electron guns are functioning.
- g) All game ROM's test - The intent of this test was to insure the integrity of all of the data in all of the game ROM's. When the ROM's for a game were originally generated there was an algorithm performed on each 1K block of data. Each of these calculations, a form of CRC (cyclic redundancy check similar to a check sum), produces a 16-bit word. These words are stored, along with a Gremlin part number, in the first ROM. When this test is run all of these 16-bit CRC words are re-generated and are compared to the known values stored in the table in the first ROM. If one of these newly calculated values does not match its corresponding stored value then the system kicks out an error which amounts to the message "Bad ROMs" followed by one or more bad part numbers of that ROM that was found in mis-match. If all ROM's are good the system quickly proceeds on the next test.

- h) System inputs test - These inputs are referred to as "System inputs" simply because they control system functions, such as credit accumulation, coinage options, game configuration, etc. The diagnostic user may check to see that the coin switches, service switch, and option "DIP" switches are functioning properly. The "Open" and "Closed" switch notation applies here as described earlier.
- i) Game controls test - The names of the controls that the game player would use to control the action on the screen is what this test was designed to check. Make sure that when hands are off of the controls all of the switches are "Open". When a particular control is twisted, pushed, turned, or whatever, watch to see that the status of that control, and only that particular control, changes to reflect the action on the control panel.
- j) Sounds/Voice test - The final phase displays each type of sound on the screen accompanied by the actual audio sound. The final sequence is Voice. The test runs through the entire vocabulary of the game.

## 2. Troubleshooting

The previous section described the basic sequence of the G-80 self-test system. This section details how to use the self-test in troubleshooting the G-80 card cage.

As in any troubleshooting procedure, we first want to eliminate as many possibilities as we can. So, for the purpose of this discussion, we'll assume that the power supply and monitor have already been checked and perform properly. (For monitor problems, check the monitor manual for your game. Power supply troubleshooting will follow this discussion.) Now, we can isolate the problem further by checking each of the G-80 boards. Let's look at a typical check-out procedure for the boards.

### a) CPU BOARD

Before we start our procedure for the CPU board, we can eliminate two possible boards right away. These are the Sound and Speech boards. By removing these boards first, we'll find out two things immediately. 1) The Speech and Sound Boards are probably good, if the original problem remains. 2) That either the Speech or Sound Board, or both, are defective, if the original problem clears up.

Doing this isolates the problem still further to just three boards. That's a better place to start. Now, we can plug the CPU Board into the extender board and insert it into any slot on the mother board. This enables you to place any other board in the top slot for easier access.

Now activate the G-80 self-test. Observe the red LED on the CPU Board. If it lights and remains lit, this tells us that one of the CPU scratch pad RAMs, U26-U29, is probably bad.

To find which one, replace them, one at a time and run the self-test again each time. If the LED lights and flashes, this indicates a problem somewhere on the CPU Board. Now we have to isolate further. Begin by using an oscilloscope to check the following levels:

1) RESET pin 26 of the Z80A should be high, or about 5 volts.

If it is low, the Z80A will lock up--trace the signal back to U30, pin 13, U23, pins 1 and 2, and the rest of the reset circuit, U12, Q5 and Q6.

2) Next, look at the C LOCK INPUT, pin 6 of the Z80A. On this pin there must be a 4 MHz clock signal that swings between 0 and 5 volts. If it is anything else, check the clock circuit on the video board, and follow it to the CPU Board through U19 and U18.

3) Then, check for a high level on pins 24, 17 and 16 on the Z80A. These are the WAIT, NMI and INT signals, respectively. If any are low, trace the cause of this through the signal's respective circuit.

4) Next, look at the outputs of U34, a 74LS244. These are pins 3, 5, 7, 9, etc., and if any are floating, suspect U34 as being defective.

5) Then, verify that the input signals on U36 and U38 are present on the outputs of the chips. If any outputs are missing or floating, suspect U36 or U38.

6) If the original problem was that the game would not coin-up, check U6, pins 8 and 11, U39, pin 9, U16, pin 12 and U7, pin 12 for level changes when the coin switch is activated. Also, verify that the coin counter advances when the switch is triggered on connector P1, pins 1 and 3. If any or all player control switches do not operate the game, suspect U5.

These tests can be made quickly by running the self-test again and observing the input port display. When a player or control switch is activated, the display will change from "0" (open) to "C" (closed), indicating a closed switch contact.

Up to this point, we've run a series of tests to check-out the CPU Board. If the results prove good, our problem is more than likely in either the Video or EPROM Board. Let's proceed to the Video Board first.

b) VIDEO BOARD

First, run the self-test again to see if it reveals a bad video RAM. The display indicates which RAM is defective. Replace it and re-start the test. The memory should now be OK. If the test shows another bad RAM, replace that RAM. If the test still indicates another bad RAM, U33, a 74S233, could be defective. Replace it, and run the test again. The memory should now pass. Verify that the color RAM, U9, is OK by observing the color pattern at the end of the self-test. If any colors are missing or the display is incorrect, suspect U9, U11, U7 or U8.

On some G-80 Video Boards, you'll see the VIC replacement board. As was mentioned earlier, this board is, in part, the equivalent circuit of the VIC chip. It is a simple circuit consisting of a number of counters and multiplexers for generating video timing and for addressing video RAM. When troubleshooting a video board with the VIC Boards, be careful that the pins on the board do not bend and that they make good contact with their socket. The 40-pin socket may need to be replaced if no other problem is found on either the VIC or Video Board.

To troubleshoot a Video Board with either a VIC chip or board, verify first that all address lines to the VIC socket have active signals present on pins 12, 13, 14, 23 and 29. All these signals

must be rapid clock pulses. Follow the outputs of the VIC chip or board through U39, U40 and U38 to the address lines on the RAMs. Again, these lines must be pulsing high and low.

Sometimes, the RAM self-test does not reveal a bad RAM, even though the picture is still incorrect. To locate the defective RAM, ground pin 14 of each RAM, the output pin, and observe the display. When you ground the defective RAM's output, the picture will break up even more in that part of the display that was originally distorted. This usually indicates that this RAM is bad. Replace it and re-run the self-test.

Suspect the VIC chip or board if the game has a vertical or horizontal sync problem-- for example, if the picture rolls and adjusting the monitor does not affect the display. Finally, it is important that the following ICs on the video board are of the "74S" series, not "74LS". The ICs are U38-74S283, U42 and U43-74S175, U45-74S74, U53-74S163 and U60-74S04. Now, let's discuss the EPROM Board and see how we can isolate a problem on it.

#### c) EPROM BOARD

As before, run the self-test to see if it indicates a bad EPROM. If it does, replace the chip and re-run the test. If all EPROMs show good, begin checking the address lines to be sure none are pulled high, low or are floating. Check for a possible short on the data lines, and make sure no EPROM pins are bent or are making poor contact with the socket.

Finally, check for the active signals on the inputs to U30 and U24. These two chips select and enable each EPROM. Then, verify that the signal labelled BUFFER on pins 1 and 19 of U25, is active low.
